In this paper, we present a novel method for content adaptation and video summarization fully implemented in compressed-domain. Firstly, summarization of generic videos is modeled as the process of extracted human objects under various activities/events. Accordingly, frames are classified into five categories via fuzzy decision including shot changes (cut and gradual transitions), motion activities (camera motion and object motion) and others by using two inter-frame measurements. Secondly, human objects are detected using Haar-like features. With the detected human objects and attained frame categories, activity levels for each frame are determined to adapt with video contents. Continuous frames belonging to same category are grouped to form one activity entry as content of interest (COI) which will convert the original video into a series of activities. An overall adjustable quota is used to control the size of generated summarization for efficient streaming purpose. Upon this quota, the frames selected for summarization are determined by evenly sampling the accumulated activity levels for content adaptation. Quantitative evaluations have proved the effectiveness and efficiency of our proposed approach, which provides a more flexible and general solution for this topic as domain-specific tasks such as accurate recognition of objects can be avoided.

1. Introduction

Summarization of digital videos plays essential roles in efficient content-access, browsing and retrieval of large video databases as well as effective storage, management and transmission [1–5]. In general, a good summarization should only keep the most important information while ignoring the less important ones, which consequently leads to extraction the content of interest (COI). However, it is found that objective defining of COI is difficult due to the fact that COIs are inevitably dependent on both the application domain and the users' preferences. One of the most widely investigated application is sports video summarization [10,13,14,25,34], followed by movies [5,7,21,30,35], news [18,32], surveillance [6], home videos [28] and web videos [19,24]. Regarding the users' preferences, personalized and user-adaptive summarization techniques are introduced and can be found in [10,11,28].

Video summarization generally involves four main components, including video segmentation, key frame extraction, COI extraction, and summary generation. Segmentation is used to determine shots and sub-shots in original videos for further processing [6,12,13], in which shot boundary detection is usually employed [1,8]. Normally, histogram and frame differences are measured and decision is then made via simple thresholding or complex classifying techniques for shot boundary detection [8]. Key frames are defined as most representative frames in each shot, and many techniques have been proposed for the extraction of them [5,6,11,37,38] while frame similarity can be measured by using simple histogram distance [1,7,30,32,39] and mutual information etc. [8]. Extraction of COIs including objects and activities can be solved by introducing user-attention model and domain knowledge [3,6,16]. As for summary generation, combining of key frames, video segments, or even a complex layout of these frames whose sizes are determined by their contained information may be considered [18]. Recent literature surveys on relevant techniques can be found in a number of sources [2,17,20,36].

According to the information used in determining COIs, video summarization methods can be categorized into two main groups, i.e. “internal summarization” and “external summarization” [17]. The prior utilizes only information extracted from the video, including image features [7,14,15,20,26,30,32], audio [32–34], camera motion [8,12] and object motion [1,7,13,16]. In contrast, the latter supports interactive processing by employing additional information such as manual annotation of the video used in MPEG-7 descriptors [32] and knowledge about the users to achieve personalized summarization [10,11,28].

In addition to low-level features, high-level semantics are also extracted for more effective video summarization as it believes that these semantics can help to extract more accurate COIs. These COIs include static and moving objects and activities at higher level, where representative techniques are involved including...
(facial) object detection, tracking, event classification and audio analysis [6,8,13,14,17,18,22]. Generally, clips of more human objects are considered to have more importance and hence assigned with higher ranks. Since the defined objects and activities are solely application dependent, such as human objects under surveillance environment and normal/abnormal activities at an airport, models and approaches for the summarization of general video contents are desired.

In this paper, we propose a new content adaptation algorithm for video summarization, which is basically an internal summarization solution. Firstly, video summarization is modeled as extraction of COIs, which is further emphasized by using human objects under motion activities. Two inter-frame measurements are then applied for frame categorization via fuzzy decision. Secondly, human objects are detected using Haar-like features. With frame categorization results and detected human objects, each frame is assigned with an activity level to represent its importance for summarization. Continuous frames of same category are then grouped to form a motion activity which has converted the original video into a series of motion activities. Thirdly, under an adjustable quota of summarization size, representative frames in each activity are determined by evenly sampling the accumulated activity level to adapt with the activity-driven content changes.

The remaining part of this paper is organized as follows: In Section 2, video summarization is modeled as extraction of useful COIs in which frame categorization is presented in details. Section 3 describes the definition of activity level and extracted series of motion activities, on the basis of extracted human objects and frame categorization results. Experimental results and discussions with quantitative evaluations are given in Section 4, and finally brief conclusions are drawn in Section 5.

2. Modeling

In this section we will model the elements in extracted COIs for content adaptation, based on which frames are classified into several categories including shot changes, motion activities and others. This categorization is achieved by two inter-frame measurements. This on the one hand solves the problem of shot boundary detection. On the other hand, it provides useful information to rank the importance of frames for summarization.

To design effective techniques for video summarization, one important requirement is the COIs extracted should be closely related with the video contents. In general, video sources are captured to cover scenes of people’s daily life. As a result, the COIs need to be defined in a way where such scenes can be modeled. There are two common elements involved in modeling these scenes, including objects and activities (events). The prior normally refers to both human and other entities, and the latter is generally caused by movement of objects and cameras. Some examples to show relationships between these objects and activities are given below:

(a) Static objects (no event or camera motion), like a painting, a flower, and a movie star, etc.
(b) Objects under camera motions, such as pan to a football field and zoom into a player, etc.
(c) Objects in motion activities, such as people swimming, students reading and a man driving.
(d) Objects under camera motion while in an event.

Since deep understanding of these objects and activities are purely domain-specific tasks, we avoid going to any further and try to provide a more general solution for video summarization. Consequently, our tasks are constrained in identifying human objects and corresponding camera and object motions rather than exactly recognizing the objects and motion activities. By measuring these extracted objects and activities, COIs are then obtained for video summarization.

To detect the above motion activities, one apparent indicator is that these activities will lead to large frame difference in video frames. However, as we know, shot changes including cuts and gradual transitions will also generate large frame difference. Therefore, the video frames need to be classified into at least five categories including cut, gradual transition, camera motion, object motion and others. In the following, we will discuss the principles in classifying these five categories of frames.

If we consider video frames as sequential images, the inter-frame difference (IFD), namely frame distortion metric in [9], will be high when shot changes occur. Normally, this difference will remain low if there are no such shot changes. As for cut, this change can be identified by a large peak in the IFD curve which lasts for only one frame. For gradual transitions, however, there will be multiple peaks which are relative high but generally lower than the height of the peak as a cut. Regarding frames without shot changes, their IFD values should be very low except those containing apparent motions. Here camera motion usually leads to higher IFD values than that of object motion as it refers to overall change of pixel positions. Although camera motion may cause large IFD values in counting co-sited pixel difference, the overall similarity of the frames remains high. Therefore, global similarity of images (GSI) can be employed to filter such cases from real shot changes. Please note that accurate definitions of GSI and IFD are given in the next section, based on the extracted DC-images from MPEG video. For boundary frames of cuts, their GSI values are small as the boundary frames are apparent different. For boundary frames of gradual transitions, their GSI values will become smaller when the interval between the frames increases. If there is no large motion and shot changes involved, the GSI values between frames will become large. Regarding large object motion, it may lead to intermediate values of both IFD and GSI which makes it different from other patterns.

Table 1 illustrates the appearances of IFD and GSI values over five categories of frames, from which we can clearly find that these two measures are capable of classifying frames into our defined categories. Although both gradual transition and large object motion will generate intermediate values of IFD and GSI, they can be distinguished by considering IFD and GSI in varying intervals. In gradual transitions, larger interval between frames will produce higher IFD values and lower GSI values, and smaller intervals will lead to lower IFD values and higher GSI values. While for object motion, IFD and GSI values under varying frame intervals do not satisfy these appearances.

To help understand how IFD and GSI values change under various frame categories, Fig. 1 illustrates some examples in which the

</tr>
</tbody>
</table>
data is extracted from test set of TRECVID’08 [40]. The frame numbers in the plots are for index purpose only, as the curves are compacted with intermediate points being omitted for better visualization effect. The frame ranges for the three sequences “BG_36528”, “BG_34413” and “BG_35148” in determining these values are [1575,1945], [120,225], and [2,205], respectively. As seen, frame categories of cut and others can be clearly identified.

Although sometimes it is difficult to distinguish between camera motion and large object motion (see Fig. 1b), such inaccuracy will not degrade our results as both these motion activities will be ranked the same level for summarization as discussed in the next section.

3. Frame categorization

Frame categorization is to classify video frames into five categories by using the principles as illustrated in Table 1. For the input videos compressed in MPEG format, we implement the whole process in compressed-domain for efficiency. The high efficiency is achieved due to the fact that only partial decoding of the video is required and the time-consuming inverse discrete cosine transform (IDCT) is avoided. Actually, both IFD and GSI are attained on the basis of our extracted DC-images. Since all the macroblocks are intra-coded in I-frames, the corresponding DC-images can be directly extracted. For P-frames and B-frames, their DC-images are obtained via weighted motion compensation as proposed in [23]. As each DC value corresponds to the average pixel value inside the related block, the DC-image provides a low-resolution version of the original frame, which presents a scaled-down visual content platform for further analysis.

If we define $Y_{dc}^{(i)}$ as the corresponding DC-images of luminance component for the $i$th frame, for two given frames $i$ and $j$, their IFD value is defined using the Soergel distance as follows [41]:

$$IFD(i,j) = \frac{\sum_{k} |Y_{dc}^{(i)}(k) - Y_{dc}^{(j)}(k)|}{\sum_{k} \max [Y_{dc}^{(i)}(k), Y_{dc}^{(j)}(k)]},$$

where $k$ is the index of the elements in the DC-images. Since all the elements in each DC-image are non-negative, we can easily have $IFD(i,j) \in [0,1]$ where larger IFD values indicate more difference between the two frames and vice versa. If the overall illumination of the image is low, a small change within frames may result in a large IFD value. On the other hand, a larger change is required to generate the same IFD value over frames of high illumination conditions. For example, if the average luminance of the image is 200, the required intensity change should be 40 to obtain a IFD value of 0.2. To achieve the same IFD value, the intensity change of 10 is sufficient if the average luminance of the image becomes 50. Consequently, IFD value provides certain degree of robustness to adapt with illumination changes over frames.

As seen, IFD values are defined in a way to measure the sum of co-sited block difference hence it is inevitably sensitive to block motions that makes the contents inconsistent. To overcome this drawback, we intend to introduce GSI as frame correlation which is implemented by phase correlation on extracted DC-images for efficiency [33]. For two DC-images $Y_{dc}^{(i)}$ and $Y_{dc}^{(j)}$, its phase correlation is defined as follows, where $\mathcal{F}(\cdot)$ denotes Fourier transform:
\[ I(i,j) = \frac{1}{3} \left[ \frac{1}{3} (Y(i)Y(i)) + \frac{1}{3} (Y(i)Y(i)) + \frac{1}{3} (Y(i)Y(i)) \right] \]

Afterwards, the global peak of maximum amplitude is determined over \( I(i,j) \) surface, and the corresponding amplitude which belongs \([0,1]\) is then taken as the similarity between two DC-images as defined in (3).

\[ GS(i,j) = \arg \max_{(k,l)} [I(k,l)]. \] (3)

Apparently, we also have \( GS(i,j) \in [0,1] \) and larger \( GS \) value refers to higher similarity and vice versa.

Examples of extracted DC-images and their associated original images in four consecutive video frames are shown in Fig. 2, where significant intensity changes can be found in the last two frames. The measurements of \( IFD \) and \( GS \) values for each consecutive pairs of the DC-images are also given. Since there are very limited content changes in the two frames before the cut, a low \( IFD \) value of 0.282 and a high \( GS \) value of 0.908 are found. When the cut occurs, a rather high \( IFD \) value of 0.765 and a very low \( GS \) value of 0.105 are obtained indicating apparent content changes associated. Due to significant change of intensity, the two post-cut frames appear very different with a pretty high \( IFD \) value of 0.805, even higher than the \( IFD \) value during the cut. However, thanks to the robustness of \( GS \) in measuring frame similarity, a relative high value of 0.774 still suggests consistent contents of the two frames.

With the defined \( IFD \) and \( GS \) values, five fuzzy membership functions (FMF) \( \Omega(i+1) \) are defined for frame categorization as presented below, where \( 0 < d_1 < d_2 < 1 \) and \( 0 < s_1 < s_2 < 1 \) are four constant parameters. For simplicity, we also denote \( d_i = IFD(i,i + 1) \) and \( s_i = GS(i,i + 1) \), where \( i \) is the frame index. The frame is then classified as the category of the maximum membership value over the five FMFs. This is different from the work in [29] where FMF is employed for fuzzy content representation. According to the principles in Table 1, FMFs for cut and others category are defined as follows:

\[ \Omega_{i+1}(\text{cut}) = \begin{cases} 1, & \text{if } d_i < d_1 \land s_i > s_2, \\ d_i/d_2, & \text{if } d_i > d_1 \land s_i > s_2, \\ s_i/s_2, & \text{otherwise}. \end{cases} \] (4)

\[ \Omega_{i+1}(\text{others}) = \begin{cases} 1, & \text{if } d_i < d_1 \land s_i > s_2, \\ d_i/d_1, & \text{if } d_i > d_1 \land s_i > s_2, \\ s_i/s_2, & \text{otherwise}. \end{cases} \] (5)

In (4), the FMF is defined to reflect the fact that frames in the category others tend to have small \( d \) but large \( s \) values, i.e., low frame difference and high inter-frame similarity. If the \( d \) is small enough and \( s \) is sufficient large, i.e., \( d_1 \leq d_i \land s_1 \geq s_2 \), it is determined as others with 100% membership degree. Otherwise, the degree is linearly degraded. Since the visual appearance of cut is of large \( d \) and small \( s \), which is opposite to that of others, hence the FMF for frame category cut in (5) is defined in a similar way, but in a different logic of (4).

To further classify camera motion, object motion and gradual transition cases, two flags, \( f_{\text{cut}}(i,i + 1) \) and \( f_{\text{cut}}(i,i + 1) \), are attained below, where \( step > 1 \) is a large frame interval

\[ f_{\text{cut}}(i,i+1) = \begin{cases} \text{true}, & \text{if } IFD(i,i+2\text{step}) > IFD(i,i +1), \\ \text{false}, & \text{otherwise}. \end{cases} \] (6)

\[ f_{\text{cut}}(i,i+1) = \begin{cases} \text{true}, & \text{if } GS(i,i+2\text{step}) < GS(i,i +1), \\ \text{false}, & \text{otherwise}. \end{cases} \] (7)

Again, according to the principles in Table 1, FMF for frame categories of gradual transition and camera motion determined as follows: If \( f_{\text{cut}}(i,i+1) \lor f_{\text{cut}}(i,i+1) \), \( \Omega_{i+1}(\text{cut}) = \Omega_{i+1}(\text{cam}) = 0 \); Otherwise, we have
orientation and scale. Although the whole set of Haar-like features note the difference of dark and light regions. As a result, they can be used for their accuracy, robustness and efficiency [31]. The Haar-like features are determined like a group of templates which determine if \(d_i \in [d_1, d_2] \land s_i \in [s_1, s_2]\), \(d_i \notin [d_1, d_2] \land s_i \in [s_1, s_2]\), \(d_i \in [d_1, d_2] \land s_i \notin [s_1, s_2]\), or \(d_i \notin [d_1, d_2] \land s_i \notin [s_1, s_2]\), otherwise.

\[
\Omega_{i+1}(gt) = \begin{cases} 
1, & \text{if } d_i \in [d_1, d_2] \land s_i \in [s_1, s_2], \\
\min(\frac{d_2}{d_i}, \frac{d_i}{d_1}), & \text{if } d_i \notin [d_1, d_2] \land s_i \in [s_1, s_2], \\
\min(s_i/s_2, s_i/s_1), & \text{if } d_i \in [d_1, d_2] \land s_i \notin [s_1, s_2], \\
\min(d_2/d_i, d_i/d_1) \cdot \min(s_2/s_1, s_i/s_1), & \text{otherwise}, 
\end{cases}
\] (8)

\[
\Omega_{i+1}(cam) = \begin{cases} 
1, & \text{if } d_i \in [d_1, d_2] \land s_i \geq s_2, \\
\min(t_2/d_i, t_i/d_1), & \text{if } d_i \notin [d_1, d_2] \land s_i \geq s_2, \\
s_i/s_2, & \text{if } d_i \in [d_1, d_2] \land s_i < s_2, \\
\min(t_2/d_i, t_i/d_1) \cdot s_i/s_2, & \text{otherwise}. 
\end{cases}
\] (9)

In Eq. (8), if \(d_i \notin [d_1, d_2]\), we have either \(d_1 < d_i\) or \(d_i > d_2\), and the part of corresponding fuzzy likelihood for \(d_i\) is then defined as min \((t_2/d_i, t_i/d_1)\). Similar rules are applied to \(s_i\), i.e. when \(s_i \notin [s_1, s_2]\), the part of its corresponding fuzzy likelihood is determined as min \((s_2/s_i, s_i/s_1)\). In Eq. (9), please note that even the likelihood part for \(d_i\) is similar to that defined in Eq. (8), the range of \(s_i\) is different, and this difference will help to identify these two cases.

Also, FMF for the frame category of object motion is defined as follows: If \(f_{IFD}(i, i+1) + f_{ECO}(i, i+1)\), \(\Omega_{i+1}(om) = 0\); Otherwise, we have

\[
\Omega_{i+1}(om) = \begin{cases} 
1, & \text{if } d_i \in [d_1, d_2] \land s_i \geq s_1, \\
\min(d_2/d_i, d_i/d_1), & \text{if } d_i \notin [d_1, d_2] \land s_i \geq s_1, \\
s_i/s_1, & \text{if } d_i \in [d_1, d_2] \land s_i < s_1, \\
\min(d_2/d_i, d_i/d_1) \cdot s_i/s_1, & \text{otherwise}, 
\end{cases}
\] (10)

As can be seen, parameters \(d_1, d_2, t_1, t_2, s_1, s_2\) form another group to threshold \(GSI(\cdot)\) values, and parameters \(s_1\) and \(s_2\) form another group to threshold \(GSI(\cdot)\) values. Each parameter is determined by using Bayesian minimum error classification rules as follows: Taking \(d_1, d_2\) as an example, firstly we calculate \(p(\text{others} | \text{IFD})\) and \(p(\text{non-others} | \text{IFD})\) as conditional probability learnt from a training set. Secondly, the threshold \(d_1\) is optimally decided in (11) below

\[
d_1 = \arg \min_{d_1} \left[ \int_0^\tau p(\text{non-others} | \text{IFD}) \, d(\text{IFD}) + \int_\tau^1 p(\text{others} | \text{IFD}) \, d(\text{IFD}) \right],
\] (11)

where the first and second parts of (11), respectively, denotes errors caused by false alarms and missing classifications when the decision is made where \(\text{IFD}(\cdot) < \tau\) refers to others. Finally, we have determined that \(d_1 = 0.06, \, d_2 = 0.75, \, s_1 = 0.1\) and \(s_2 = 0.93\).

4. Human object detection and COIs extraction

In this Section, we will firstly discuss how to detect human objects in videos. On the basis of detected human objects and frame categorization results, secondly we will present the details in extracting useful COIs containing human objects and motion activities.

4.1. Human object detection

To detect human objects within videos, Haar-like features are used for their accuracy, robustness and efficiency [31]. The Haar-like features are determined like a group of templates which denote the difference of dark and light regions. As a result, they can be considered as features containing edge information at different orientation and scale. Although the whole set of Haar-like features is large, during a training process only a small sub-set is learned from positive and negative examples for face detection. In our system, the implementation of Haar face detector in OpenCV is used for the detection of human objects [42].

For efficiency, face detection is only applied to I-frames on the corresponding DC-images of luminance component, \(Y_{100}\). Since the size of a face in the DC-image will become one-eighth of its original size in width and height, the extracted DC-image is enlarged to enable successful detection of small face regions in the DC-image. Also a small window of \(10 \times 10\) pixels is used as the initial search window with a step of 10% of the initial size, i.e. increasing 1 pixel in both width and height. Finally, the number of detected face objects is denoted as \(n_i\), which will be employed in video summarization in the next step.

4.2. Activity-driven COIs extraction

As described in the previous sections, COIs should be defined in a way that human objects and apparent motion activities are a focus. To this end, for each frame \(i\) we assign \(r(i)\) as a rank of importance to be selected as COIs which is defined as follows:

\[
r(i) = \left[ IFD(i, i+1) \right]^{1/(1+n_i)}.
\] (12)

Apparently, larger values of \(IFD(i, i+1)\) and \(n_i\) produce higher ranks of \(r(i)\) as they respectively refer to more content changes (caused by motion activities, etc.) and more detected human objects. On the contrary, smaller values of \(IFD(i, i+1)\) and \(n_i\) generate lower ranks of \(r(i)\). When there is no human objects detected, i.e. \(n_i = 0\), we simply have \(r(i) = IFD(i, i+1)\). When \(IFD(i, i+1) = 0\), we have \(r(i) = 0\) no matter how \(n_i\) changes. This is useful to skip frames which have no difference to its prior ones, such as embedded static or black frames in videos.

Since both camera motion and large object motion yield large values of \(IFD(i, i+1)\), they will lead to high ranks of \(r(i)\) for further processing. In other words, both of them are treated equally in ranking frames for summarization thus the inaccuracy in classifying these two categories can be ignored. As for frame category of others, its rank values are low due to very small \(IFD(i, i+1)\) values that have been attached. In addition, it can be seen that for shot changes including both cut and gradual transitions, the associated rank values will also be high due to large \(IFD(i, i+1)\) values contained. However, these frames can be processed specifically by making use of the frame category information which will be addressed in the next section.

According to the sequence “BG_2408.mpg” from TRECVID’07 test set, we have illustrated the change of \(r(i)\) between \(IFD(i, i+1)\) under varying detected number of human objects \(n_i\) as shown in Fig. 3. As seen, larger \(n_i\) will help to increase the rank value \(r(i)\) and makes \(r(i) > IFD(i, i+1)\). In other words, it is the human objects (represented by detected face masks) and large inter-frame difference (caused by motion activities) that leads to high rank values for effective video summarization. To this end, our approach is activity-driven which shows content adaptation with COIs.

4.3. Generating summarization through content adaptation

After frame categorization, the original video \(V\) can be represented by a series of motion activities \(A\), including camera motion, object motion, and others, i.e. \(V = \{A_1, A_2, \ldots, A_M\}\), and \(M\) is the total number of extracted motion activities. These activities may be separated by shot changes like cut and gradual transitions. Frames in the category of camera and object motion will be included in the generated summarization, but those gradual transitions will be excluded. Two boundary frames of cut effects will be merged with their directly adjacent motion activities. The reason that we put others within the activity series is that frames in this category may be also included in the summarization, though under a coarse re-sample rate due to much low rank values of \(r(i)\).
In fact, \( r(i) \) is employed to determine the importance of the frame to be included in the summarization [43]. For each motion activities \( A_m \), the sum of its average motion activity level \( R_m \) is determined by (13) where \( l_{m1} \) and \( l_{m2} \) denote the frame boundary of \( A_m \):

\[
R_m = \sum_{i=l_{m1}}^{l_{m2}} r(i) .
\]  

(13)

The overall activity level of the whole sequence \( R_{all} \) is then obtained as

\[
R_{all} = \sum_{m=1}^{M} R_m .
\]

(14)

To provide certain flexibility, an adjustable upper limit of the summarization ratio \( \lambda \) (between 0 and 1) is allowed in video summarization, i.e. the target video will have frames no more than a fixed percentage of the original video. Next, we will discuss how to assign the size quota to all detected activities \( A_m \) for video summarization. Let \( L \) be the length of the original video in frames, the length of the summarization video should be no more than \( \lambda L \) frames. Therefore, each rank unit corresponds to \( \lambda L/R_{all} \) frames inside the summarization video. For each activity \( A_m \), the frame quota \( q(m) \) assigned for it is determined as

\[
q(m) = \lambda L R_m R_{all}^{-1} .
\]

(15)

In the following, we will discuss how to determine the specific \( q(m) \) frames in \( A_m \) for summarization. If \( q(m) = 0 \), the whole clip of \( A_m \) is ignored. If \( q(m) = 1 \), the middle frame of \( A_m \) at the index \((l_{m1} + l_{m2})/2\) is selected. Otherwise, both the first and the last frames of \( A_m \) are selected. When \( q(m) > 2 \), the remaining frames to be selected for summarization is determined via an iterative process as follows: If frame \( i_1 \) has been selected, the next frame to be selected is \( i_2 \), and \( i_2 \) should be the first frame satisfying that the accumulated activity level between \( i_1 \) and \( i_2 \) is no less than \( \lambda L/R_{all} \)

\[
\sum_{i_1 \leq i \leq i_2} r(i) \geq \lambda L/R_{all} > \sum_{i_1 \leq i \leq i_2} r(i) , \quad i \in (l_{m1}, l_{m2}) .
\]

(16)

Please note that the above re-sampling is nonlinear and unevenly distributed over frames. In terms of the accumulated activity levels, however, the sampling process could be regarded as even. If a video clip contains high activity level caused by camera/object motion and detected human objects, it is re-sampled under a small interval. On the other hand, a video clip of low activity level will have a large re-sample interval due to smooth contents it has contained. In an extreme case, static frames of no changes in comparison with its prior frame will be skipped. This is consistent with the expectations of our human perceptions in viewing videos while extracting COIs and identifying importance over sequence of videos. Some interesting results are illustrated and discussed in the next section.

5. Results and discussions

The proposed model and techniques have been fully tested by using the data set from the well-known TRECVID evaluation series. In this section, the results on frame categorization and video summarization are illustrated and analyzed. Quantitative evaluations are achieved objectively by using our extracted manual ground truth maps and the details are presented below.

5.1. Data set and evaluation criteria

The test set in TRECVID series contains videos compressed in MPEG-1 format, and the frame size is 352 × 288 pixels. In total 15 video sequences are used in our experiments with nearly 524,000 frames (about 5.8 h at 25 fps). These test sequences cover a wide range of courses including movies, news, education programs and historical archives.

According to the results of frame categorization and video summarization, two different evaluations are used in our system. To achieve objective and quantitative measurements of the performance, these results are compared with our manually extracted ground truth maps. The ground truth maps are produced for each sequence which contains a series of video segments in varying frame categories. Each such segment is represented as \( (id, type, i_1, i_2, w) \) where \( id \) and \( type \) denote its index and frame category, respectively; \( i_1 \) and \( i_2 \) refer to the start and end frames; \( w \in [0,1] \) denotes average importance of the segments to be selected as COIs. The most important content is assigned with \( w = 1 \) and the least important one with \( w = 0 \). The parameter \( w \) is manually determined as follows: Firstly, we have three independent viewers and they view each sequence and assign a weight to every video segment. To enable accurate weighting, the viewers need glance over the whole sequence before they rank the video segments. Finally, the average score from them is then utilised as
the determined $w$. Accordingly, quantitative analysis of these evaluations are achieved and discussed below.

5.2 Evaluation of frame categorization

To evaluate the performance of frame categorization, the results attained are converted to the similar format as defined in the ground truth, which contains $(\text{id}, \text{type}, i_1, i_2, \text{rank})$ where $\text{rank}$ denotes the average activity level within the frame interval $[i_1, i_2]$ and the other elements are the same as those in ground truth maps. On the average the overall accuracy of frame categorization is about 88.3%. By comparing the results with ground truth frame by frame, a confusion matrix is obtained to show the accuracy of frame categorization as presented in Table 2.

As seen, in general the most accurate results are achieved in classifying frames in the categories of cut and others, followed by object motion and camera motion. And the worst results are obtained in classifying gradual transition effects. One apparent reason here is that both cut and others can be defined clearly with little ambiguity, such as its appearances listed in Table 1. While for the other three categories, they share some common appearances hence the lower accuracy in classification. Although there are relative large errors in classifying frames in the categories of gradual transition, camera motion and object motion, such errors will not necessarily lead to poor performance in video summarization, especially for the misclassification errors between camera motion and object motion. However, inaccurately classifying motion activities into gradual transitions may lead to critical problems as it may lead to content lost when such gradual transitions are removed during summarization.

In addition, it is found in Table 2 that motion activities including both camera motion and object motion form more than 80% of the video contents. This has also proved that our activity-driven scheme has the potential to extract the most meaningful contents from the videos for effective summarization. On the contrary, shot changes only occupy less than 2.5% of frames in the original videos. Regarding frames in the category of others, they appear as a percentage about 16% in the test videos.

The parameter $\text{rank}$ in obtained results and $w$ in ground truth maps are used to evaluate the accuracy of frame importance which is measured by using activity levels. For each motion activity, the error of frame ranking is $(i_2 - i_1 + 1)\text{rank} - w$. The relative overall error of frame ranking $e_f$ is defined as

$$e_f = \frac{\sum_{\text{id}} (i_2^{(\text{id})} - i_1^{(\text{id})} + 1) \left| \text{rank}^{(\text{id})} - w^{(\text{id})} \right|}{\sum_{\text{id}} R^{(\text{id})}}$$

where $R^{(\text{id})}$ denotes the sum of frame importance of motion activity $\text{id}$ in the ground truth maps as defined below

$$R^{(\text{id})} = w^{(\text{id})} \left( \frac{i_2^{(\text{id})} - i_1^{(\text{id})} + 1}{i_2^{(\text{id})} - i_1^{(\text{id})} + 1} \right).$$

Table 3 gives $e_f$ values under various frame categories from which we can see that our extracted activity level is closely matched with the frame importance defined in the ground truth. This one hand has demonstrated that activity levels indeed can be used to measure frame importance in such a context. On the other hand, it also reveals that large errors in frame categorization (about 11.7%) only cause a quite small error in $e_f$ at about 4.1%. This again has shown that misclassification of frame categories will not certainly lead to degradation of summarized videos.

5.3 Evaluation of video summarization

The most important measurement in evaluation of video summarization is to examine the completeness that all the COIs have been included, i.e. inclusions in the summary, and this is usually defined as a percentage of activities included in the generated summary. Here, two different evaluations are obtained including: (i) inclusion of motion activities $IN_{\text{m}}$, and (ii) inclusion of frame accuracy $IN_{\text{f}}$. The first one is an overall evaluation to the inclusion
of COIs and a COI is included if the summarized video contains at least one frame of the COI. Certainly this is a coarse evaluation which is further improved in the second evaluation where the inclusion of each activity is defined as a ratio between [0,1] below. Please note that we intend to generate automatic and objective evaluation in which subjective scoring by human observers is avoided as those used in many other systems such as [27].

For a given motion activity in the ground truth, its associated frame quota $q_{gt}$ can be decided by

$$q_{gt}(id) = \frac{idLR_{gt}(id)}{R_{gt,all}}, \quad R_{gt,all} = \sum_{id} R_{gt}(id),$$

where parameter $\lambda$ and $L$, respectively, denote a given summarization ratio and the length of the original video as defined in (15).

The overall inclusion of frame accuracy $IN_{f}$ is then attained as

$$IN_{f} = \frac{\sum_{id} n(id)q_{gt}(id)}{\sum_{id} q_{gt}(id)},$$

where $n(id)$ denotes number of frames within the $id^{th}$ motion activity in the ground truth that has been included in the summarized video.

Fig. 4 plots the changes of activity inclusion $IN_{f}$ and frame inclusion $IN_{e}$ under varying summarization ratio $\lambda$. According to the results in Fig. 4, several facts can be summarized below. Firstly, $IN_{f}$ is found more accurate than $IN_{e}$ due to the fact that $IN_{f}$ is determined by a percentage of frames included. Therefore, incompleteness of frame inclusion may lead to a low $IN_{f}$ value but still a high $IN_{e}$ value. In other words, $IN_{f}$ is more accurate in measuring the inclusion of summarized video. Secondly, decreasing summarization ratio will lead to lower inclusion scores, and $IN_{f}$ values will degrade more than $IN_{e}$ values. Thirdly, it seems $\lambda = 15\%$ is a good tradeoff between a low summarization ratio and a high inclusion values.

With a fixed summarization ratio of $\lambda = 15\%$, the performance of our proposed algorithm is compared with two others including the work reported in [8,27] and the results are listed in Table 4. For consistent comparisons, the recursive process in clustering of key frames in [8] stops when the sum of extracted key frames no more than our predefined quota. For simplicity, linear fusion is employed in which all the weights for different videos are set as 0.25 in implementing the algorithm in [27]. As can be seen, our method yield slightly better results than the one reported in [27] under linear fusion scheme. Since the weights in [27] can be adjusted for better performance, the overall performances of the two algorithms are quite comparative. However, fewer features are needed in our algorithm and it is also nearly three times faster than the one in [27]. Regarding the method in [8], it generates the worst results in this test due to the fact that extraction of high-level semantics such as face detection is excluded. Taking this into consideration, the result is not bad as it can be further improved in video summarization context.

Note, an average face detection rate achieved is only 74.6% using the Haar detector, and three reasons to explain this are given as follows: The first one is the pose variation of faces in video, as Haar detector performs better only in detecting frontal faces. The second reason is the limited size of image for face detection, especially using DC-image, the smoothed small version of the original frame image. The third reason is that we only detect faces in I-frames, thus faces in B- and P-frames may be missed. Although the face detection rate is less than 75%, the $IN_{f}$ and $IN_{e}$ values achieved in Table 4 is 82–85%. This has clearly shown that our proposed approach can still generate good results even the detected faces is less accurate. In other words, it means that our method does not rely on face detection. As a result, it can be applied to general videos even without human objects for content-adaptive summarization.

Finally, it is worth mentioning that our system can achieve a processing speed of 128.3 fps, i.e. more than 5.1 times faster than real-time play of the video. The percentage of time spend in our algorithm is summarized in Table 5 in which we can find that nearly 32% of computational load is used in calculating CSI, even under fast implementation of Fourier transform. Partial decoding of MPEG videos occupies about 30% of the computation capacity. These two need to be further improved.

### 6. Conclusions

In this paper, we described a new algorithm for video summarization, which provides a more flexible and general solution for this topic as domain-specific tasks like exactly recognizing the objects and activities are avoided. In general our approach can be applied to any videos, although the presence of human objects helps to refine the weights in generating content-adaptive summarization. Our COI-based modeling is found not only useful in frame categorization but also helpful in activity-driven content adaptation for effective video summarization. We have introduced two measures for objective evaluation of summarization results, and it is found that our proposed methodology can generate very promising results under such a context. In addition, we have also demonstrated that compressed-domain processing is not only efficient but also effective in such a context. Further improvement could be made by introducing new techniques towards more effective presentation of COIs of varying activity levels.
